Polarimetric radar measurements of a large-scale smoke plume from distant Canadian wildfires

Characterizing both shape and orientation distributions of particles in the atmosphere can be aided by polarimetric radar measurements. In the case of a roughly horizontally homogeneous distribution of particles, the azimuthal variability of the polarimetric radar measurements can also provide unique information about the particle shapes and orientation. A large smoke plume over the midwestern United States, originating from a series of wildfires in western Canada during August 2018, provides such a case. S-band polarimetric radar measurements intercepting this plume on 8 August 2018 show a clear azimuthal pattern of maxima and minima in the reflectivity ($Z_H$), differential reflectivity ($Z_{DR}$), differential phase ($\Phi_{DP}$), and correlation coefficient ($\rho_{HV}$). The maxima in $Z_{DR}$, $Z_H$, and $\rho_{HV}$ occur for the azimuthal angles roughly perpendicular to the wind flow, suggesting oriented prolate-like smoke particles within the plume. In addition, asymmetries in the azimuthal distribution of $\Phi_{DP}$ indicate that the simultaneously transmitted radiation exhibits unique depolarization signatures at different viewing angles, with the maximum depolarization occurring where $Z_{DR}$ is maximized. These signatures suggest that the particles have a specific preferred orientation: their long axes are aligned roughly parallel to the wind, and they have a non-zero mean canting angle with respect to the surface. Potential applications of these measurements for charactering the smoke particle properties as well as applications to hydrometeor measurements are also discussed.
